

# A Mean-Variance Explanation of FDI Flows to Developing Countries\*

Eva Rytter Sunesen

Department of Economics, University of Copenhagen

2 Maj 2007

## Abstract

The shift in the empirical literature from the traditional low-return explanation of limited foreign direct investment (FDI) in certain developing countries to a focus on country risk has been largely ad hoc and unsupported by a theoretical framework. In addition, the majority of empirical studies implicitly assume that countries are independent. By solving the mean-variance optimisation problem of foreign investors taking global and regional business cycle effects into account, the model implies that FDI is driven by the *risk-adjusted* rate of return. Moreover, the model highlights the need to be very precise in the definition of both return and risk. First, local return should be adjusted for the risk premiums required by investors to compensate for global and regional covariance risk. Second, the relevant risk measure should be idiosyncratic risk rather than overall risk, since the latter overstates country risk by including structural and systematic components. Our empirical results find that FDI inflows are indeed driven by the risk-adjusted rate of return and that there is a positive net benefit from global integration. Also, Asian and African countries seem to benefit from their regional location.

# 1 Introduction

While a large part of the empirical literature on FDI has focussed mainly on the traditional low-return explanation of limited FDI inflows to certain developing countries, more recent studies have attempted to control for the risk of investing abroad. The importance of risk stems from the fact that, in the face of the uncertainty connected to foreign investments, the objective of investors is to maximise the expected return on their investment. This means that in addition to the rate of return, the variance of return becomes a critical element in the investment decision. Recent empirical studies have therefore included various economic, political and commercial risk measures but the selection of risk proxies has been largely ad hoc and unfounded in economic theory.

Moreover, most empirical papers implicitly assume that countries are independent. However, an important feature of the world economy is the increased global and regional integration due to intensified trade and investment relations among countries. The increased integration of countries is likely to give rise to increased business cycle synchronisation and such systematic patterns in the covariance of returns should be incorporated in the investor's optimisation problem.

This paper offers a theoretical framework for FDI that takes both return and risk into account, and which applies global and regional factors to model the interdependence between countries. This framework allows us to decompose total risk into covariance risk and idiosyncratic risk. *Covariance risk* can be defined as the variance in a country's return that is caused by common global and regional factors.<sup>1</sup> The global factor captures movements in the underlying forces that drive the economies (i.e. oil price shocks, productivity shocks, interest rate shocks, etc.). On the other hand, shocks that affect adjacent countries owing to similarities in production, export and trade structures would be captured by the regional factor. *Idiosyncratic risk*, on the other hand, is what remains after having adjusted for both structural and systematic components of total risk. Changes in macro-

---

<sup>1</sup>Systematic risk and undiversifiable risk have both been used in the literature as synonyms for covariance risk. However, these terms rely on the existence of costless diversification opportunities and on the existence of a large market portfolio. The definition of covariance risk applied in this paper does not, and it continues to be relevant even when the investor invests only in a few countries and where there are certain entrance costs. See Cochrane (2001), Chapter 7.

economic policy implementation, internal conflicts or structural changes affecting return in a particular country will be captured by the idiosyncratic risk factor.

Overall, our theoretical model predicts that FDI inflows are driven by the *risk-adjusted rate of return*. Moreover, once we take the interdependence between countries into account, we must be very careful in our definition of both return and risk. First, return should include the spillovers from the global and regional investment climate. Second, country risk should be adjusted for covariance risk in order to get a more precise measure of idiosyncratic risk since ignoring such systematic comovements in returns exaggerates the measure of country risk.

We test the implications of our structural model on the net flow of FDI into a cross-section of 60 developing countries. We find that FDI inflows are driven by the risk adjusted rate of return only when we obtain a precise measure of idiosyncratic risk; that is once we control for both global and regional covariance risk. We also find that there is a relatively large and positive net effect from global integration. On the regional level, there is a positive net effect of being located in Asia and (to a lesser extent) in Africa. In Latin America, on the other hand, the regional return component is exactly balanced by the risk premium and there is thus no net effect of being located in this region. The results are robust to the correction for the possible bidirectional relationship between FDI and growth.

The paper proceeds as follows. Section 2 summarises the theoretical arguments for global and regional business cycle synchronisation. Section 3 solves the investor's optimisation problem using a mean-variance optimisation framework under three different scenarios of interdependence between alternative FDI locations: no correlation (the traditional view), the presence of a global factor in a country's return (global business cycle) and, lastly, the coexistence of a global and regional component in the country returns (global and regional business cycles). Section 4 sets out the econometric modelling of the FDI relation and tests the implications of the structural model based on the risk measures derived in Sunesen (2006). Finally, Section 5 summarises and concludes.

## 2 Global and Regional Business Cycles

The phenomenon of globalisation, the rising economic and financial integration of the world economy, has received tremendous attention in recent years. The increased globalisation is likely to have given rise to comovements in economic aggregates and thus to business cycle effects.

The leading explanation for business-cycle synchronisation is (bilateral and total) trade, which captures the flow of technological transmission and the extent to which a country is exposed to global shocks.<sup>2</sup> However, as pointed out by Frankel and Rose (1998) and Heathcote and Perri (2002), among others, one could also expect increased trade to result in increased sectoral specialisation (through returns to scale, etc.). If the primary business cycle shocks are sector-specific, then countries with greater similarity in sectoral structures and exports would tend to have more correlated business cycles, other things equal. This means that if adjacent countries have more similar industrial structure, export good composition or initial endowments (human capital, physical capital, arable land, etc.) one might expect regional business cycle comovement.

Figure A1-A3 in the Appendix suggest that there are regional similarities in the distribution of wealth (important to the income-generating process), in the composition of natural capital (suggestive of initial endowments) and in the distribution of economic activity (correlated with industrial structures) that might give rise to regional business cycle synchronisation due to asymmetric shocks to world prices - fluctuations in the prices of primary, capital and intermediate goods, and in the world real interest rate.<sup>3</sup>

Figure A1 shows the regional distribution of wealth divided into natural capital, produced capital and intangible capital. Wealth in African countries stems mainly from natural capital whereas intangible capital adds up to more than half of total wealth in Latin America and Asia. Figure A2 shows the composition

---

<sup>2</sup>Another frequently referenced explanation is financial integration but in light of the poorly developed financial markets in most developing countries we focus on the trade mechanism. We refer to Baxter and Kouparitsas (2004) for further references on the many potential explanations of business cycle comovement.

<sup>3</sup>Interest rate disturbances might cause significant business cycle fluctuations in highly indebted countries, the so-called HIPC countries, most of which are located in Sub-Saharan Africa and Latin America.

of natural capital wealth. The non-renewable subsoil resources are particularly important in Latin America but weigh less heavily in Africa and Asia. Forested areas account for a large share of natural capital in Africa while dependency on land is strongest in Asia. Finally, Figure A3 depicts the distribution of economic activity. While more than a quarter of the income generated in Africa and Asia stems from agriculture, hunting, forestry and fishing, the number is only 15% in Latin America. Finally, while the three regions have comparable levels of economic activity in the mining, construction and transport sectors, African manufacturing is largely underdeveloped compared with Latin America and Asia.

Together the data presented here suggest that we should expect both global and regional business cycle synchronisation. This is supported by a vast amount of empirical evidence. Kose, Otrok and Whiteman (2003) find that there is a distinct global business cycle that accounts for a large fraction of business-cycle variability in developed countries, whereas regional and idiosyncratic factors are more important in developing economies. The finding of a global business cycle is supported by Albuquerque, Loayza and Servén (2002), while Baxter and Kouparitsas (2004) and IMF (2005, Chapter 2) find evidence of regional business cycle comovement.

### **3 A Theoretical Model of Risk and Return**

The presence of common global and regional factors in local returns means that there will be some systematic pattern in the covariance of returns that the investor can exploit in order to get a more precise measure of return and risk. The theoretical model builds on the mean-variance portfolio model associated particularly with Tobin (1958, 1965) and Markowitz (1952). The model assumes that multinational enterprises (MNEs) estimate the expected profitability of choices among risky assets by looking at the mean and variance provided by combinations of those assets.<sup>4</sup>

---

<sup>4</sup>This only leads to expected utility maximisation if investor's utility function depends only on the means and the variance of wealth (quadratic utility function) and if returns are normally distributed.

### 3.1 The Optimisation Problem

We make two simplifying assumptions that make the optimisation framework suitable for the investment decision of MNEs. First, direct investors typically have a relatively long investment horizon, where the entry decision comes first and where the investor then adjusts the size of his investment according to the expected profitability of investment in the particular country. Empirically, this means that FDI inflows in some periods might become negative, which will happen if dividend payment from the host country to the source country is higher than the investments made in that year. In financial terms this means that we allow for "short sales". This assumption also ensures that all countries are in the portfolio; some will be held long (receive positive amounts of net FDI) and others will be held short (receive negative amounts of net FDI).

Second, we assume that there is riskless lending and borrowing. This assumption can be justified by the fact that the majority of foreign investors are large-scale MNEs that come from industrialised countries with highly developed capital markets. Relative to investing in developing countries where the risk of investment is so much higher, assuming that there is riskless lending and borrowing at the world interest rate is probably not a bad approximation.

Under the assumption of risk-less lending and borrowing, the tangency portfolio is the optimal portfolio of risky assets that is preferred to all other portfolios, see Elton et al. (2003, Chapter 6). According to Sharpe (1963) the optimal portfolio is then the portfolio with the greatest ratio of excess return (expected return minus the risk-free rate) to standard deviation that satisfies that the sum of the proportions invested in the country equals 1. Substituting the constraint into the objective function means that we can solve the problem by maximising the Sharpe Ratio (SR):

$$\max_x SR = \frac{\sum_{i=1}^N x_i (\bar{R}_i - R_f)}{[\sum_{i=1}^N x_i^2 \sigma_i^2 + \sum_{i=1}^N \sum_{j=1, j \neq i}^N x_i x_j \sigma_{ij}]^{\frac{1}{2}}}, \quad (1)$$

where  $x_i$  is the share of FDI going to country  $i$ ,  $\bar{R}_i$  is the expected rate of return to

investment in country  $i$ ,  $R_f$  is the riskless rate of return (the world interest rate),  $\sigma_i^2$  is the variance of return to investment in country  $i$ , and  $\sigma_{ij}$  is the covariance between returns in country  $i$  and country  $j$ . Setting the derivative with respect to  $x_m$  equal to zero and rearranging yields

$$\frac{dSR}{dx_m} = -[\lambda x_m \sigma_m^2 + \sum_{j=1, j \neq m}^N \lambda x_j \sigma_{mj}] + (\bar{R}_i - R_f) = 0, \quad (2)$$

where

$$\lambda = \frac{\sum_{i=1}^N x_i (\bar{R}_i - R_f)}{\sum_{i=1}^N x_i^2 \sigma_i^2 + \sum_{i=1}^N \sum_{j=i}^N x_i x_j \sigma_{ij}} = \frac{\bar{R}_p - R_f}{\sigma^2(R_p)}, \quad (3)$$

and  $\bar{R}_p$  is the expected return on the portfolio and  $\sigma^2(R_p)$  is the variance of  $R_p$ . Defining  $Z_m = \lambda x_m$  and substituting it for  $\lambda x_m$  yields a system of  $N$  simultaneous equations for  $N$  unknown variables ( $Z_m$ ):

$$\bar{R}_i - R_f = Z_m \sigma_m^2 + \sum_{j=1, j \neq m}^N Z_j \sigma_{mj}, \quad m = 1, \dots, N. \quad (4)$$

### 3.2 Adjusting for Global and Regional Interdependence

In an optimisation model of  $N$  countries the analyst must provide estimates of  $N$  expected returns,  $N$  variances of returns and  $N(N-1)/2$  covariances of return. To simplify the problem, we utilise the empirical observation of global and regional interdependence summarised in the previous section to formulate index models that will provide a structural solution of the model.<sup>5</sup> We show here the derivations for the multi-index model since the single-index model follows directly. To our knowledge this paper is the first to offer an explicit solution of a multi-index model. In constructing the indices we make the identifying assumption that countries are

---

<sup>5</sup>Index models have frequently been used to simplify the nature of interdependence between countries; see among others Rajan and Friedman (1997), Kose, Otrok and Whiteman (2003), and Albuquerque, Loayza and Servén (2002).

small relative to the world economy, which implies that local factors may have a global component but that the reverse is not true. Also, we assume that countries are small relative to the regional economy and therefore that local factors may have a regional component but that the reverse is not true.

The *multi-index model* assumes that returns move together partly because of economy wide changes and partly because of their belonging to a regional subgroup.<sup>6</sup> Let  $\omega$  be an index of global market performance defined as  $\omega = \alpha_\omega + \varepsilon_\omega$  where  $\alpha_\omega$  is the global rate of return and  $\varepsilon_\omega$  captures global shocks. By symmetry, let  $\tau_k$  be the index of regional market performance defined as  $\tau_k = \alpha_{\tau_k} + \varepsilon_{\tau_k}$ , where  $\alpha_{\tau_k}$  is the regional return and  $\varepsilon_{\tau_k}$  captures regional shocks in region  $k$ ,  $k \in K$  where  $K$  is the set of regions. We can now define the rate of return to investment in country  $i$  as

$$R_i = \alpha_i + \beta_{i\omega}\omega + \sum_{k=1}^K \beta_{i\tau_k} I_{ik} \tau_k + u_i, \quad (5)$$

where  $\alpha_i$  is the country-specific rate of return, and  $\beta_{i\omega}$  is the degree of global integration,  $\beta_{i\tau_k}$  is the degree of the degree of regional integration, and  $I_{ik}$  is an indicator of regional belonging that takes on the value one if country  $i$  belongs to region  $k$  and zero otherwise.

While a multi-index model of this kind can be employed directly, the model would have some very convenient mathematical properties if the indexes were orthogonal,  $E(\omega - \alpha_\omega)(\tau_k - \alpha_{\tau_k}) = E[\varepsilon_\omega \varepsilon_{\tau_k}] = 0$ , and if the residual was uncorrelated with two indexes,  $E[u_i(\omega - \alpha_\omega)] = E[u_i \varepsilon_\omega] = 0$  and  $E[u_i(\tau_k - \alpha_{\tau_k})] = E[u_i \varepsilon_{\tau_k}] = 0$ .<sup>7</sup> Under these assumptions total risk can be expressed as

$$\sigma_i^2 = \beta_{i\omega}^2 \sigma_\omega^2 + \sum_{k=1}^K \beta_{i\tau_k}^2 I_{ik} \sigma_{\tau_k}^2 + \sigma_{u_i}^2, \quad (6)$$

where  $\sigma_\omega^2$  is the variance of global return, and  $\sigma_{\tau_k}^2$  is the variance of return in

---

<sup>6</sup>There might be other reasons why one could observe covariance in the returns to investment in two countries. Examples could be important common trading partners, high dependence on a similar export product, natural resource abundance, climatic zones, etc. We will ignore these factors for now.

<sup>7</sup>In the Cohen and Pogue (1967) notation, this means that we apply the multi-index model in its diagonal form.

region  $k$ . This formulation ensures that total risk can be decomposed into global and regional covariance risk,  $\beta_{i\omega}^2 \sigma_\omega^2$  and  $\beta_{i\tau_k}^2 \sigma_{\tau_k}^2$ , as well as idiosyncratic risk,  $\sigma_{u_i}^2$ .

Substituting for  $\sigma_i^2$  and  $\sigma_{ij}$  in (4) and solving for  $Z_i$  yields

$$Z_i = \frac{1}{\sigma_{u_i}^2} [(\bar{R}_i - R_f) - \beta_{i\omega} C_\omega^* - \sum_{k=1}^K \beta_{i\tau_k} I_{ik} C_{\tau_k}^*], \quad (7)$$

where  $C_\omega^* = \sigma_\omega^2 \sum_{j=1}^N Z_j \beta_{j\omega}$  and  $C_{\tau_k}^* = \sum_{j=1}^N Z_j \beta_{j\tau_k} \sigma_{\tau_k}^2$ .

### 3.3 Implications

**Scenario 1.** If there is no correlation between countries ( $\beta_{i\omega} = \beta_{i\tau_k} = 0, \forall k \in K$ ), the share of FDI going to country  $i$ ,  $Z_i$ , will be given by

$$Z_i = \frac{1}{\sigma_{\varepsilon_i}^2} [\bar{R}_i - R_f].$$

The term  $\bar{R}_i - R_f$  reflects excess return over the risk-free rate of return, and it can therefore be interpreted as the risk premium imposed on country  $i$ . Since our empirical analysis will be based on a cross-section of countries we can set the risk-free rate equal to zero without loss of generality. We can then simplify the expression

$$Z_i = \frac{1}{\sigma_{\varepsilon_i}^2} \bar{R}_i = \frac{\alpha_i}{\sigma_{\varepsilon_i}^2}, \quad (8)$$

where  $\alpha_i$  is the expected rate of return to investment in country  $i$ , and  $\sigma_{\varepsilon_i}^2$  is the total risk of investing in country  $i$  ( $\sigma_{\varepsilon_i}^2 = \sigma_i^2$ ). The result shows that FDI flows are driven by the risk-adjusted rate of return rather than return per se.

**Scenario 2.** In the presence of a common movement in returns due to a global business cycle ( $\beta_{i\tau_k} = 0 \forall k \in K$ ), the single index model gives

$$Z_i = \frac{1}{\sigma_{\varepsilon_i}^2} [\bar{R}_i - R_f - \beta_{i\omega} C_\omega^*].$$

For a country to be held long,  $Z_i > 0$ , we must require that  $C_\omega^* < (\bar{R}_i - R_f) / \beta_{i\omega}$ . We can therefore interpret  $C_\omega^*$  as the global "cut-off point".  $(\bar{R}_i - R_f) / \beta_{i\omega}$  is the standardised global risk premium; i.e. the risk premium relative to country  $i$ 's

contribution to global covariance risk (also called excess return to beta). Again, we can rewrite the expression to get a more intuitive interpretation:

$$Z_i = \frac{\alpha_i}{\sigma_{e_i}^2} + (\alpha_\omega - C_\omega^*) \frac{\beta_{i\omega}}{\sigma_{e_i}^2}, \quad (9)$$

where  $\alpha_\omega$  is the global return,  $\sigma_{e_i}^2$  is the risk of investing in country  $i$  adjusted for global covariance risk ( $\sigma_{e_i}^2 = \sigma_i^2 - \beta_{i\omega}^2 \sigma_\omega^2$ ), and  $\beta_{i\omega}$  is the degree of global spillovers. The first term is the risk-adjusted rate of return familiar from Scenario 1. The second term reflects the country-specific net effect of global integration, which will depend on the combined sign of  $(\alpha_\omega - C_\omega^*)$  and  $\beta_{i\omega}$ . If the global return is higher than the global cut-off point,  $\alpha_\omega > C_\omega^*$ , there is a net benefit of global integration and the country therefore gains from being positively correlated with the global index,  $\beta_{i\omega} > 0$ .

Since the portfolio includes both countries that are positively and negatively correlated with the world economy the investor gains from diversifying across countries. However, since countries are not perfectly correlated and since there is a finite number of developing countries (each MNE is typically only present in a small number of countries) investors cannot diversify away all covariance risk.

**Scenario 3.** In the presence of both global and regional business cycle effects, the relevant regression is

$$Z_i = \frac{\alpha_i}{\sigma_{u_i}^2} + (\alpha_\omega - C_\omega^*) \frac{\beta_{i\omega}}{\sigma_{u_i}^2} + \sum_{k=1}^K (\alpha_{\tau_k} - C_{\tau_k}^*) I_{ik} \frac{\beta_{i\tau_k}}{\sigma_{u_i}^2}, \quad (10)$$

where  $\beta_{i\tau_k}$  is the degree of regional spillovers,  $C_{\tau_k}^*$  is the regional risk premium, and  $\sigma_{u_i}^2$  is total risk adjusted for both global and regional risk components ( $\sigma_{u_i}^2 = \sigma_i^2 - \beta_{i\omega}^2 \sigma_\omega^2 - \sum_{k=1}^K \beta_{i\tau_k}^2 I_{ik} \sigma_{\tau_k}^2$ ). By symmetry, if the regional return outweighs the regional covariance risk ( $\alpha_{i\tau_k} - C_{\tau_k}^* > 0$ ), a country that is positively correlated with the regional business cycle will benefit from its regional location.

The investor experiences a second diversification gain by investing in countries that are positively as well as negatively correlated with the regional economy. Since the regional return components are assumed to be uncorrelated once we control for the common comovement due to the global business cycle, there is no additional diversification benefit from diversifying across regions.

## 4 Empirical Estimation

In this section we take the structural model of FDI to the data. In the most elaborated case, return in country  $i$  at time  $t$  is

$$R_{it} = \alpha_{it} + \beta_{i\omega}\omega_t + \sum_{k=1}^K \beta_{i\tau_k} I_{ik} \tau_{kt} + u_{it}. \quad (11)$$

Since direct measures of the return to FDI in developing countries is not available, we follow the methodology in Sunesen (2006) to obtain the local, global and regional return components as well as the relevant covariance and idiosyncratic risk measures. We proxy return by growth in GDP per capita,  $g_{it}$ , and estimate

$$g_{it} = x'_{it} \delta + \varepsilon_{it}, \quad \varepsilon_{it} \sim IID(0, \sigma_{\varepsilon_i}^2) \quad (12)$$

where  $x_{it}$  is a vector of slowly-moving growth determinants and  $\varepsilon_{it}$  is the growth residual. The country-specific return,  $\alpha_i$ , can then be proxied by averaging  $x'_{it} \hat{\delta}$  over time, and  $\sigma_{\varepsilon_i}^2$  is interpreted as conditional risk (total risk adjusted for economic fundamentals). To take out the global return component we estimate

$$\hat{\varepsilon}_{it} = \beta_{i\omega} \omega_t + e_{it}, \quad e_{it} \sim IID(0, \sigma_{e_i}^2) \quad (13)$$

where  $\hat{\omega}_t$  can be identified as the first principal component from a principal components analysis (PCA) of  $\hat{\varepsilon}_{it}$ , and  $\beta_{i\omega}$  is the factor loading  $\sigma_{e_i}^2$  is conditional risk adjusted for global covariance risk. Averaging  $\omega_t$  over time gives the global return component,  $\omega$ . By symmetry, we adjust for regional spillovers by undertaking a PCA of  $\hat{\varepsilon}_{it}$  for each region individually and estimate

$$\hat{e}_{it} = \sum_{k=1}^K \beta_{i\tau_k} I_{ik} \tau_{kt} + u_{it}, \quad u_{it} \sim IID(0, \sigma_{u_i}^2) \quad (14)$$

where  $\tau_{kt}$  is the first principal component and  $\beta_{i\tau_k}$  is the factor loading from the PCA of region  $k$ .

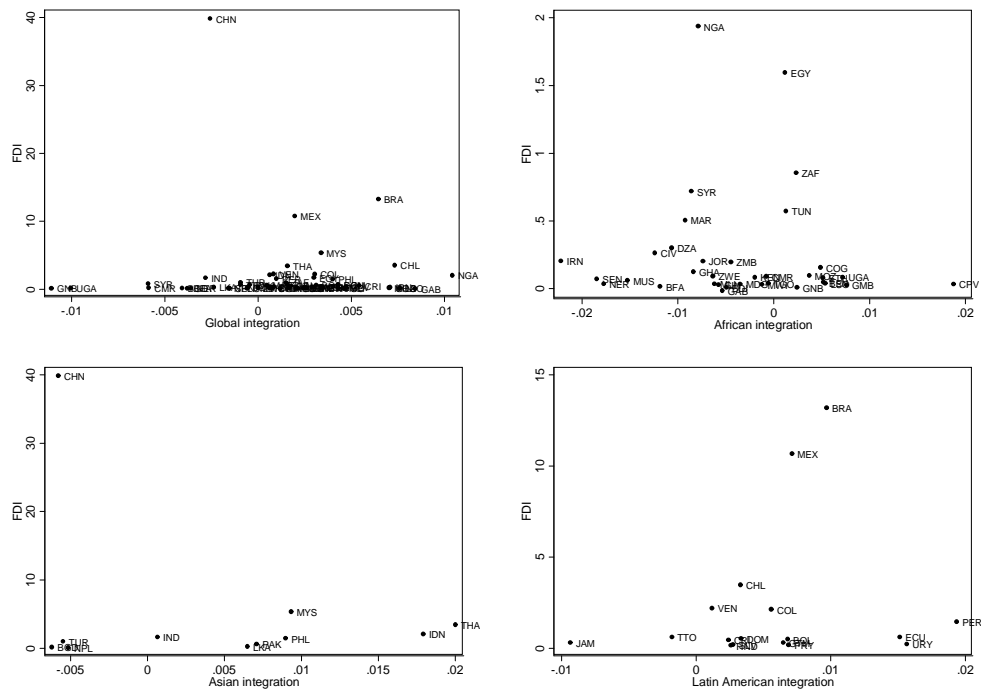

The great advantage of undertaking the PCA in two steps is the precise interpretation and identification of the principal components as capturing global and regional spillovers. In addition, the methodology ensures that the crucial assumptions of the multi-index model are satisfied: the covariance between the two indexes is zero, the residual is uncorrelated with each index, and the covariance between the residual  $i$  and the two indexes is zero. A remaining problem is that the correlations between the regional indices are not zero by construction. However, since we have already adjusted for the global factor, the problem is likely to be small. In fact, the correlation between Latin America and Asia is 0.09, the correlation between Latin America and Africa is 0.07, while the correlation between Africa and Asia is 0.10. Given these relatively low numbers, we ignore these correlations in our empirical estimation of the structural FDI relation.

## 4.1 Results

Before we turn to the regression results, it is informative to look at some partial effects. The first graph in Figure 1 shows the correlation between FDI and the degree of global integration,  $\beta_{i\omega}$ , for the 63 countries initially included in the sample. The positive relationship between the two variables indicates that the global return component more than outweighs the risk premium imposed to compensate for global covariance risk. China is a clear outlier and, as in the majority of empirical FDI studies, China has been excluded from the sample due to its dominant share of FDI into developing countries and Asia in particular. Not only has this status been achieved in a relatively short period of time, see UNCTAD (1994), but concerns have also been raised about the reported magnitude of FDI inflows into China. The World Bank (1996) reports that the overestimation may be more than 25% of annual FDI flows.

The correlation between FDI and the degree of regional integration in Africa,  $\beta_{i\tau_{AFR}}$ , depicted in the second graph is close to zero. In Asia, on the other hand, the degree of regional integration,  $\beta_{i\tau_{ASIA}}$ , seems to be positively correlated with FDI inflows. The last graph shows that Brazil and Mexico are huge FDI recipients compared with other Latin American countries, and their outlier status is confirmed by the test for multiple outliers in multivariate data in Hadi (1992, 1994).

Figure 1: Effects of Global and Regional Integration on FDI Inflows

Note: The figure depicts cross-plots of FDI inflows against the degree of global integration,  $\beta_{\text{int}}$ , and the degrees of regional integration  $\beta_{it}$ . Source: FDI data is from the UNCTAD database.  $\beta$ s are from Sunesen (2006).

This finding is probably not surprising considering the size of these countries as well as their close ties with the United States, which makes them less dependent upon global and regional markets.

We now turn to the regression analysis and we estimate the three cross-section equations using Ordinary Least Square (OLS) for the sample of 60 countries.

$$\text{Scenario 1.} \quad \omega_i = c_0 \frac{\hat{\alpha}_i}{\hat{\sigma}_{\varepsilon_i}^2} + \varepsilon_i$$

$$\text{Scenario 2.} \quad \omega_i = c_0 \frac{\hat{\alpha}_i}{\hat{\sigma}_{e_i}^2} + c_1 \frac{\hat{\beta}_{i\omega}}{\hat{\sigma}_{e_i}^2} + e_i$$

$$\text{Scenario 3.} \quad \omega_i = c_0 \frac{\hat{\alpha}_i}{\hat{\sigma}_{u_i}^2} + c_1 \frac{\hat{\beta}_{i\omega}}{\hat{\sigma}_{u_i}^2} + c_2 AFR \frac{\hat{\beta}_{i\tau_{AFR}}}{\hat{\sigma}_{u_i}^2} + c_3 ASIA \frac{\hat{\beta}_{i\tau_{ASIA}}}{\hat{\sigma}_{u_i}^2} + c_4 LAC \frac{\hat{\beta}_{i\tau_{LAC}}}{\hat{\sigma}_{u_i}^2} + u_i$$

While  $c_0$  reflects the importance of the risk-adjusted rate of return (where the definition of risk varies between the three scenarios),  $c_1$  reflects the net benefit of global integration ( $\alpha_\omega - C_\omega^*$ ), and  $c_2 - c_4$  reflect the net benefit of being located in Africa, Asia and Latin America ( $\alpha_{\tau_k} - C_{\tau_k}^*$ , where  $k = AFR, ASIA, LAC$ ). Results are reported in Table 1.<sup>8</sup>

Column 1 shows the regression results based on the traditional view that FDI inflows are driven by returns,  $\alpha_i$ . Country returns enter positively but insignificant and the explanatory power is very low. In Column 2, countries are completely independent and the only determinant of FDI is the risk-adjusted rate of return. This variable turns out to be positive and insignificant and the explanatory power remains very low. In Column 3 we adjust for global interdependence and we find that there is a positive net benefit of global integration

In Column 4 we see that the more precise definition of idiosyncratic risk once we adjust for global and regional covariance risk means that the risk-adjusted rate of return is clearly identified and significant. In addition to a positive net benefit of global integration, we find that there is a strong positive net gain of being located in Asia whereas the African spillover effect is lower and less significant. The Latin

---

<sup>8</sup>A future version of this paper should take into account the fact that we use generated regressors in the regression analysis. At this point in time it is unclear what the effect on the results will be. See Pagan (1984).

Table 1: FDI Regressions (OLS estimation)

	Unconditional	Scenario 1	Scenario 2	Scenario 3
Return	2.89 [13]	0.027 [0.03]	0.027 [0.02]	0.020** [0.008]
Global integration			0.11** [0.05]	0.098** [0.04]
Asian integration				0.057*** [0.007]
Latin American integration				-0.024 [0.02]
African integration				0.020* [0.01]
Constant	0.60*** [0.1]	0.57*** [0.1]	0.42*** [0.1]	0.34*** [0.1]
R-squared	0	0.07	0.18	0.51

Note: OLS regression including 60 countries (excluding China, Brazil and Mexico). The dependent variable is average net FDI inflows from 1970-2000. Heteroscedastic consistent standard errors in brackets. \*\*\* p<0.01, \*\* p<0.05, \* p<0.1

American return factor, on the other hand, is exactly matched by the risk premium required to compensate for regional covariance risk.

## 4.2 Endogeneity Problems

The methodology in Sunesen (2006) is based on the premise that GDP growth is closely related to the return to investment and thus that growth is a main driver of FDI. However, one needs to face the question of causality since fast growing economies might also attract FDI flows as MNEs search for new market and profit opportunities. Although Hansen and Rand (2004) present empirical evidence of a bidirectional relationship between FDI and growth in the short run and support for a causal link from growth to FDI in the long run, we wish to make sure that our results are robust against possible endogeneity problems.

We therefore use the two-stage least square estimator based on a set of instruments that we expect to be highly correlated with the risk-adjusted rate of return but uncorrelated with the error term. These instruments include the current account balance, external debt as a share of GDP, international reserves and the Kaufmann et al. (2005) rule of law indicator. The first two variables are used as indicators of government credibility and political stability since the presence of

Table 2: FDI Regressions (2SLS estimation)

	Unconditional	Scenario 1	Scenario 2	Scenario 3
Return	15.1 [20]	0.074* [0.04]	0.060** [0.03]	0.033* [0.02]
Global integration			0.12** [0.05]	0.10*** [0.03]
Asian integration				0.051*** [0.01]
Latin American integration				-0.03 [0.02]
African integration				0.03 [0.02]
Constant	0.55*** [0.1]	0.50*** [0.1]	0.36*** [0.1]	0.34*** [0.1]
R-squared	-0.03	-0.14	0.05	0.47
Number of countries	60	60	60	60
Hausman test	0.3029	0.1504	0.4419	0.9553
Sargan Hansen test	0.13	0.124	0.113	0.143
Anderson canonical corr.	0.0000083	0.03	0.024	0.0099
Cragg Donald F-test	0.00000017	0.019	0.015	0.0049
Anderson-Rubin F-test	0.096	0.096	0.15	0.17
Anderson-Rubin Chi	0.06	0.06	0.096	0.095

Note: 2SLS regression including 60 countries (excluding China, Brazil and Mexico). Return is instrumented with the current account balance, external debt, international reserves and a law an order indicator. The dependent variable is average net FDI inflows from 1970-2000. Heteroscedastic consistent standard errors in brackets. \*\*\* p<0.01, \*\* p<0.05, \* p<0.1

such imbalances may weaken the availability of external credit and spur expectations of higher future tax liabilities. Also, the availability of large international reserves reflects a vital host economy and lessens the need for imposing capital constraints on foreign investors. Finally, the strength and impartiality of the legal system measures the quality of contract enforcement, the police and the courts, as well as the likelihood of crime and violence. Results are reported in Table 2.

The Sargan Hansen test informs us that our instruments are valid, and the Anderson canonical correlation test and the Cragg Donald F-test confirm that we have no problem with weak instruments. The Anderson-Rubin tests shows that return is significant in the regression. However, the Hausman tests confirms the Hansen and Rand (2004) finding that growth drives FDI and not the opposite. Hence, we can treat  $\alpha_i$  as exogenous in the regression and rely on our results in Table 1.

## 5 Summary and Conclusions

This paper applies a simplified version of the mean-variance portfolio model that explicitly takes the interdependencies of alternative investment locations into account. The model predicts that FDI inflows are driven by the *risk-adjusted rate of return* but that one should be very careful in the applied definition of both return and risk. First, in addition to the local return investors should also take the risk premium required for bearing global and regional covariance risk into account in their locational choice. Second, total risk should be adjusted for covariance risk in order to get a more precise measure of idiosyncratic risk. In the most extended model, we find that the investor diversifies his portfolio in two ways: by investing in countries that are positively as well as negatively correlated with the global business cycle, and by investing in countries that are positively as well as negatively correlated with the regional economy.

We test the implications of our structural model on the net flow of FDI into 60 developing countries. We find that FDI inflows are determined by the risk-adjusted rate of return once we adjust for global and regional covariance risk, and that there is a positive net benefit of global integration. Also, we find that there is a strong positive net gain of being located in Asia whereas the African spillover effect is lower and less significant. The Latin American return factor, on the other hand, is exactly matched by the risk premium required to compensate for regional covariance risk.

## Tables and Figures

### Figure A1. Distribution of Wealth

Source: World Bank (2005). Data is in per cent of total wealth. Natural capital is the sum of non-renewable subsoil resources, forested areas and land areas. Produced capital is the sum of equipment and machinery, structures and urban land. Intangible capital is calculated as the residual wealth and includes mainly human capital, institutional quality and social capital.

### Figure A2. Composition of Natural Capital Wealth

Source: World Bank (2005). Data is in per cent of total wealth. Subsoil assets include oil, natural gas, coal and mineral resources.

### Figure A3. Distribution of Economic Activity

Source: Data is from the National Accounts Main Aggregates Database. Data is in per cent of natural capital wealth.
